Introduction

Introduction

Focus of the talk: the implementation of a state-of-the-art econometric estimator in Stata and Mata to estimate an equation with instrumental variables techniques where sufficient instruments may not be available.

590

Motivation

Instrumental variables (IV) methods are employed in linear regression models, e.g., $y = \mathbf{X}\beta + u$, where violations of the zero conditional mean assumption $E[u|\mathbf{X}] = 0$ are encountered.

Reliance on IV methods usually requires that appropriate instruments are available to identify the model: often via exclusion restrictions.

Those instruments, **Z**, must satisfy three conditions: (i) they must themselves satisfy orthogonality conditions (E[uZ] = 0); (ii) they must exhibit meaningful correlations with **X**; and (iii) they must be properly excluded from the model, so that their effect on the response variable is only indirect.

Finding appropriate instruments which simultaneously satisfy all three of these conditions is often problematic, and the major obstacle to the use of IV techniques in many applied research projects.

Although textbook treatments of IV methods stress their usefulness in dealing with endogenous regressors, they are also employed to deal with omitted variables, or with measurement error of the regressors ('errors in variables') which if ignored will cause bias and inconsistency in OLS estimates.

Lewbel's approach

The method proposed in Lewbel (*JBES*, 2012) serves to identify structural parameters in regression models with endogenous or mismeasured regressors in the absence of traditional identifying information, such as external instruments or repeated measurements.

Identification is achieved in this context by having regressors that are uncorrelated with the product of heteroskedastic errors, which is a feature of many models where error correlations are due to an unobserved common factor.

In this presentation, we describe a method for constructing instruments as simple functions of the model's data. This approach may be applied when no external instruments are available, or, alternatively, used to supplement external instruments to improve the efficiency of the IV estimator.

Supplementing external instruments can also allow 'Sargan–Hansen' tests of the orthogonality conditions to be performed which would not be available in the case of exact identification by external instruments.

In that context, the approach is similar to the dynamic panel data estimators of Arellano and Bond (*Review of Economic Studies*, 1991) et al., as those estimators customarily make use of appropriate lagged values of endogenous regressors to identify the model. In contrast, the approach we describe here may be applied in a purely cross-sectional context, as well as that of time series or panel data.

▲□▶ ▲□▶ ▲ □▶ ▲ □▶ →

The basic framework

Consider Y_1 , Y_2 as observed endogenous variables, X a vector of observed exogenous regressors, and $\varepsilon = (\varepsilon_1, \varepsilon_2)$ as unobserved error processes. Consider a structural model of the form:

$$Y_1 = X'\beta_1 + Y_2\gamma_1 + \varepsilon_1$$

$$Y_2 = X'\beta_2 + Y_1\gamma_2 + \varepsilon_2$$

This system is triangular when $\gamma_2 = 0$ (or, with renumbering, when $\gamma_1 = 0$). Otherwise, it is fully simultaneous. The errors $\varepsilon_1, \varepsilon_2$ may be correlated with each other.

▲□▶▲□▶▲□▶▲□▶ = のへの

If the exogeneity assumption, $E(\varepsilon X) = 0$ holds, the reduced form is identified, but in the absence of identifying restrictions, the structural parameters are not identified. These restrictions often involve setting certain elements of β_1 or β_2 to zero, which makes instruments available.

In many applied contexts, the third assumption made for the validity of an instrument—that it only indirectly affects the response variable—is difficult to establish. The zero restriction on its coefficient may not be plausible. The assumption is readily testable, but if it does not hold, IV estimates will be inconsistent.

Identification in Lewbel's approach is achieved by restricting correlations of $\varepsilon \varepsilon'$ with X. This relies upon higher moments, and is likely to be less reliable than identification based on coefficient zero restrictions. However, in the absence of plausible identifying restrictions, this approach may be the only reasonable strategy.

The parameters of the structural model will remain unidentified under the standard homoskedasticity assumption: that $E(\varepsilon \varepsilon' | X)$ is a matrix of constants. However, in the presence of heteroskedasticity related to at least some elements of X, identification can be achieved.

In a fully simultaneous system, assuming that $cov(X, \varepsilon_j^2) \neq 0, j = 1, 2$ and $cov(Z, \varepsilon_1 \varepsilon_2) = 0$ for observed *Z* will identify the structural parameters. Note that *Z* may be a subset of *X*, so no information outside the model specified above is required.

The key assumption that $cov(Z, \varepsilon_1 \varepsilon_2) = 0$ will automatically be satisfied if the mean zero error processes are conditionally independent: $\varepsilon_1 \perp \varepsilon_2 | Z = 0$. However, this independence is not strictly necessary.

Single-equation estimation

In the most straightforward context, we want to apply the instrumental variables approach to a single equation, but lack appropriate instruments or identifying restrictions. The auxiliary equation or 'first-stage' regression may be used to provide the necessary components for Lewbel's method.

In the simplest version of this approach, generated instruments can be constructed from the auxiliary equations' residuals, multiplied by each of the included exogenous variables in mean-centered form:

$$Z_j = (X_j - \overline{X}) \cdot \epsilon$$

where ϵ is the vector of residuals from the 'first-stage regression' of each endogenous regressor on all exogenous regressors, including a constant vector.

where ϵ is the vector of residuals from the 'first-stage regression' of each endogenous regressor on all exogenous regressors, including a constant vector.

SQA

These auxiliary regression residuals have zero covariance with each of the regressors used to construct them, implying that the means of the generated instruments will be zero by construction. However, their element-wise products with the centered regressors will not be zero, and will contain sizable elements if there is clear evidence of 'scale heteroskedasticity' with respect to the regressors. Scale-related heteroskedasticity may be analyzed with a Breusch–Pagan type test: estat hettest in an OLS context, or ivhettest (Schaffer, SSC; Baum et al., *Stata Journal*, 2007) in an IV context.

The greater the degree of scale heteroskedasticity in the error process, the higher will be the correlation of the generated instruments with the included endogenous variables which are the regressands in the auxiliary regressions.

Empirical illustration 1

In Lewbel's 2012 *JBES* paper, he illustrates the use of his method with an Engel curve for food expenditures. An Engel curve describes how household expenditure on a particular good or service varies with household income (Ernst Engel, 1857, 1895).¹ Engel's research gave rise to *Engel's Law*: while food expenditures are an increasing function of income and family size, food budget shares decrease with income (Lewbel, *New Palgrave Dictionary of Economics*, 2d ed. 2007).

In this application, we are considering a key explanatory variable, total expenditures, to be subject to potentially large measurement errors, as is often found in applied research: due in part to infrequently purchased items (Meghir and Robin, *Journal of Econometrics*, 1992).

¹Not to be confused with Friedrich Engels, Karl Marx's coauthor. () A COUNTRY AND A

¹Not to be confused with Friedrich Engels, Karl Marx's coauthor. () Not to be confused with Friedrich Engels, Karl Marx's coauthor.

The data are 854 households, all married couples without children, from the UK Family Expenditure Survey, 1980–1982, as studied by Banks, Blundell and Lewbel (*Review of Economics and Statistics*, 1997). The dependent variable is the food budget share, with a sample mean of 0.285. The key explanatory variable is log real total expenditures, with a sample mean of 0.599. A number of additional regressors (age, spouse's age, ages², and a number of indicators) are available as controls. The coefficients of interest in this model are those of log real total expenditures and the constant term.

We first estimate the model with OLS regression, ignoring any issue of mismeasurement. We then reestimate the model with log total income as an instrument using two-stage least squares: an exactly identified model. As such, this is also the IV-GMM estimate of the model.

In the following table, these estimates are labeled as OLS and TSLS1. A Durbin–Wu–Hausman test for the endogeneity of log real total expenditures in the TSLS1 model rejects with p-value=0.0203, indicating that application of OLS is inappropriate.

∢ ⊒ ▶

The greater efficiency available with IV-GMM is evident in the precision of these estimates. However, reliance on generated instruments yields much larger standard errors than identified TSLS.²

As an alternative, we augment the available instrument, log total income, with the generated instruments, which overidentifies the equation, estimated with both TSLS and IV-GMM methods.

²The GMM results do not agree with those labeled GMM2 in the *JBES* article. However, it appears that the published GMM2 results are not the true optimum.

We illustrate the use of this method with an estimated equation on firm-level panel data from US Industrial Annual COMPUSTAT. The model, a variant on that presented in a working paper by Baum, Chakraborty and Liu, is based on Faulkender and Wang (*J. Finance*, 2006).

We seek to explain the firm-level unexpected change in cash holdings as a function of the level of cash holdings (C), the change in earnings (dE), the change in non-cash assets (dNA) and market leverage (Lev). The full sample contains about 13,000 firms for up to 35 years.

SQ Q

We seek to explain the firm-level unexpected change in cash holdings as a function of the level of cash holdings (C), the change in earnings (dE), the change in non-cash assets (dNA) and market leverage (Lev). The full sample contains about 13,000 firms for up to 35 years.

SQ Q

For purposes of illustration, we first fit the model treating the level of cash holdings as endogenous, but maintaining that we have no available external instruments. In this context, *ivreg2h* produces three generated instruments: one from each included exogenous regressor. We employ IV-GMM with a cluster-robust VCE, clustered by firm.

The resulting model is overidentified by two degrees of freedom (jdf). The jp value of 0.245 is the p-value of the Hansen J statistic.

We reestimate the model using the lagged value of cash holdings as an instrument. This causes the model to be exactly identified, and estimable with standard techniques. ivreg2h thus produces three sets of estimates: those for standard IV, those using only generated instruments, and those using both external and generated instruments. The generated-instrument results differ from those shown previously as the sample is now smaller.

 $\mathcal{O} \mathcal{Q} \mathcal{O}$

(日)

The results show that there are minor differences in the point estimates produced by standard IV and those from the augmented equation. However, the latter are more efficient, with smaller standard errors for each coefficient. The model is now overidentified by three degrees of freedom, allowing us to conduct a test of over identifying restrictions. The p-value of that test, jp, indicates no problem.

This example illustrates what may be the most useful aspect of Lewbel's method: the ability to augment an exactly-identified equation to both allow a test of over identifying restrictions and gain efficiency.

Summary remarks on ivreg2h

The extension of this method to the panel fixed-effects context is relatively straightforward, and we are finalizing a version of Mark Schaffer's xtivreg2 which implements Lewbel's method in this context.

We have illustrated how this method might be used to augment the available instruments to facilitate the use of tests of overidentification. Lewbel argues that the method might also be employed in a fully saturated model, such as a difference-in-difference specification with all feasible fixed effects included, in order to test whether OLS methods will yield consistent results.
