October 17, 2004

Draft Version

#### Abstract

The modeling of financial transaction data - price, spread, volume and duration - in an event basis is motivating a growing number of works. The first proposals, where limited to pure duration models. Then its impact on the volatility was analyzed. More recently a vector model also including volume was studied by Manganelli (2002). In this paper, we extend his work by including the bid-ask spread into the model throughout a vector autoregressive model. The conditional means of spread, volume and duration along with the volatility of returns evolve through transaction events based on an exponential formulation that we called Exponential Multivariate Autoregressive Conditional Model (EMACM).

In this new proposal, there is no constrains on the parameters. This facilitates the maximum likelihood estimation of the model and allows the use of simple likelihood ratio hypothesis tests to specify the model and obtain some clues about the interdependency structure of the variables.

Keywords: High frequency data, GARCH, autoregressive conditional multivariate models, nonlinear time series.

## 1 Introduction

The availability of high frequency databases makes possible to understand financial market dynamics (intra-day basis) and test some of hypothesis brought up by the microstructure theory. In that way, many formulations have been suggested.

Historically, we can observe three distinct phases when considering trading variables modeling. The first corresponds to the early developments made. In the second, the concepts embedded in ARCH/GARCH models, formulated in order to deal with volatility regimes in stock price returns, were applied to model other trading variables, specially the time between financial transactions (duration).

Now, in the third phase, the focus is not only on the dynamic of a specific high frequency variable, but also on the influence that exists among them. Here, the main goal is to define how the trading variables influence each other.

Regarding high frequency data models, the first development occurred in 1948 when Wold (Skandinavisk Aktuarietidskrist - On Stationary Point Process and Markov Changes) proposed to capture the dynamic presented in the conditional intensity through the use of ARMA models. In 1955, Cox (Journal of the Royal Statistical Society - Some Statistical Models Connected with Series of Events) included lagged variables in order to explain the conditional intensity. Latter, in 1980, Lewis (Advances in Applied Probability - First-Order Autoregressive Gamma Sequences and Point Processes) extended the original proposal of Cox - EARMA.

In 1998, Engle e Russell (Econometrica - Autoregressive Conditional Duration: A New Model For Irregularly Spaced Transaction Data) introduced the ACD (Autoregressive Conditional Duration) model, in which the time between events has been described as a sequence of independent random variables with a time varying mean given by a GARCH type equation. Bauwens and Veredas, in 1999, defined a stochastic process for conditional duration (latent stochastic factor), in order to capture the market information flow (non-observable variable). Later, Bauwens and Giot (2000) proposed the use of a logarithmic version of ACD models, where the non-negativity constraint wasn't necessary.

In 2000, Engle incorporated the methodology developed before, in a volatility context (UHF-GARCH). After that, in 2001, Zhang, Russell and Tsay (Econometrica - A nonlinear autoregressive conditional duration model with applications to financial transaction data) extended the original model (EACD and WACD), through the using of thresholds (multiple regimes), in order to capture the non-linearity. In a similar way, in 2001, Fernandes and Gramming (CORE - A family of autoregressive conditional duration models) added some changes to the model initially proposed by Engle and Russell, dealing with non-linearity through the application of a Box-Cox transformation over the original series.

Recently, in 2002, Manganelli (ECB Working Paper Series - Duration, Volume and Volatility impact of trades) proposed the joint modeling of different variables (duration, volume and volatility) involved in the financial transaction process by the use of Vector Autoregressive Models (VARM). That was the first time in which volume information has been explicitly modeled and the work is one of the first trials of dealing with joint behavior of trading variables.

In this paper, we extend the work of Manganelli by including the bid-ask spread into an autoregressive multivariate system and proposing an exponential formulation to the conditional mean, avoiding the adoption of constraints in the parameters when maximizing the likelihood function. We called it the Exponential Multivariate Autoregressive Conditional Model (EMACM). The structure of the coefficient matrices of the system is tested via likelihood ratio tests, answering some of the questions raised in the microstructure literature about causality and dependency among variables.

Regarding the analysis of intra-day seasonal pattern, we've found that the lowest durations (high intensity) are observed close to the opening and closing of financial market. As a consequence, the bid-ask spread and price volatility increase. In relation to the volume intra-day pattern, the highest values are observed close to the opening of transaction days, what can be explained by the fact that new information were not incorporated into price (after-market effects).

Considering the structure of the coefficient matrices, the likelihood ratio test pointed to the rejection of the hypothesis of no causality in trading day variables, since the individual formulation is strongly rejected. Here, the results show that the system seems to be variation-free as suggested by Manganelli.

That article is divided as follows. Section 2 presents the model. Section 3 describes the seasonal adjustment (off-line estimation). Section 4 brings details of the nonlinear optimization algorithms used. A Monte-Carlo simulation is carried out in Section 5 and an empirical example is shown in Section 6. Finally, Section 7 concludes.

## 2 The Model

The model proposed in this paper is called Exponential Multivariate Autoregressive Conditional High Frequency Data Model (EMACM).

Lets define $x_{i}$ as being the duration of the i-th observed financial transaction, where $x_{i}=t_{i}$ $-\mathrm{t}_{\mathrm{i}-1}$ (time space between trades) and $\mathrm{z}_{\mathrm{i}}$ as a vector of explanatory variables. Thus:

$$
\begin{equation*}
\left(x_{i}, z_{i}\right) \sim f\left(x_{i}, z_{i} \mid \Omega_{i} ; \theta\right) \tag{2.1}
\end{equation*}
$$

Where, $\mathrm{f}\left(\mathrm{x}_{\mathrm{i}}, \mathrm{z}_{\mathrm{i}} \mid \Omega_{\mathrm{i}} ; \theta\right)$ corresponds to the joint probability distribution function of $\mathrm{x}_{\mathrm{i}}$ and $\mathrm{z}_{\mathrm{i}}, \Omega_{\mathrm{i}}$ is the remaining information available until the i-th event has occurred and $\theta$ is the vector of unknown parameters.

Letting $z_{i}^{\prime}=\left(v_{i} s_{i} y_{i}\right)$, where: $v_{i}$ is the volume of i-th transaction, $s_{i}$ is the bid-ask spread and $y_{i}$ is instantaneous return. Thus,

$$
\begin{equation*}
\left(x_{i}, z_{i}\right) \sim f\left(x_{i}, v_{i}, s_{i}, y_{i} \mid \Omega_{i} ; \theta\right) \tag{2.2}
\end{equation*}
$$

Re-writing the joint probability distribution function (2.2) as the product of the conditional probability distribution, we have:

$$
\begin{equation*}
\left(x_{i}, z_{i}\right)=g\left(x_{i} \mid \Omega_{i} ; \theta_{1}\right) h\left(v_{i} \mid x_{i}, \Omega_{i} ; \theta_{2}\right) k\left(s_{i} \mid x_{i}, v_{i}, \Omega_{i} ; \theta_{3}\right) l\left(y_{i} \mid x_{i}, v_{i}, s_{i}, \Omega_{i} ; \theta_{4}\right) \tag{2.3}
\end{equation*}
$$

Equation 2.2 seems natural when the use of strategic models is considered. For example, Kyle (1985) modeled the informed traders behavior based on the effect of buy or sell orders into price, conditioning the analysis to the non-informed traders and market-makers attitude.

At the moment the information became public, it's verified a strong offer/demand pressure originated, mainly, by the action of market makers. Once the time interval among events and the volume could indicate that some traders may be using private information, the marketmakers will use that in order to prevent losses. In that way, investors who own some information that is not disseminated in market will split their trades (decreasing volumes per transaction and increasing the number of transactions per time unit - intensity), making the identification process more complicated, postponing any changes in the bid and ask prices and, consequently, in the transaction price itself.

Based on what was disposed by Kyle, it's clear the option made in favor of the relation establish by equation 2.3 , in which the causality relation is shown in figure 1 .

Figure 1 - Causality relation (duration, volume, spread and price)
Defining each one of the system components, the models can be determined separately:

- Duration:

$$
\begin{align*}
& x_{i}=\psi_{i} \cdot \varepsilon_{i} \rightarrow \varepsilon_{i} \sim \exp (1)  \tag{2.4}\\
& \psi_{i}=E\left(x_{i} \mid \Omega_{i} ; \theta_{x}\right) \tag{2.5}
\end{align*}
$$

- Duration: positive real numbers;
- Volume: analogous to the duration models.

$$
\begin{align*}
& v_{i}=\phi_{i} \cdot \eta_{i} \rightarrow \eta_{i} \sim \exp (1)  \tag{2.6}\\
& \phi_{i}=E\left(v_{i} \mid \Omega_{i} ; \theta_{v}\right) \tag{2.7}
\end{align*}
$$

- Volume: positive real numbers;
- Bid-ask spread: analogous to the duration models.

$$
\begin{equation*}
s_{i}=P_{\text {sell }}-P_{b u y} \tag{2.8}
\end{equation*}
$$

Where, $\mathrm{P}_{\text {buy }}$ corresponds to the buy price offered by the market makers $\left(\mathrm{P}_{\text {sell }}\right.$ is analogous).

$$
\begin{align*}
& s_{i}=\varphi_{i} \cdot \varpi_{i} \rightarrow \varpi_{i} \sim \exp (1)  \tag{2.9}\\
& \varphi_{i}=E\left(s_{i} \mid \Omega_{i} ; \theta_{s}\right) \tag{2.10}
\end{align*}
$$

- Spread: positive real numbers;
- GARCH:

$$
\begin{align*}
& y_{i}=\sigma_{i} \cdot \varsigma_{i} \rightarrow \quad \varsigma_{i} \sim N(0,1)  \tag{2.11}\\
& \sigma_{i}^{2}=E\left(y_{i}^{2} \mid \Omega_{i} ; \theta_{y}\right) \tag{2.12}
\end{align*}
$$

- Volatility: positive real numbers;

Thus, the conditional mean of the Exponential Multivariate Autoregressive Conditional High Frequency Data Model being considered could be defined as follows:

$$
\begin{equation*}
\ln \left(\mu_{i}\right)=\gamma+\sum_{k=1}^{q} A_{k} \ln \left(\mu_{i-k}\right)+\sum_{m=0}^{p} B_{m} \ln \left(\tau_{i-m}\right) \tag{2.13}
\end{equation*}
$$

Where, $\mu_{\mathrm{i}}{ }^{\prime}=\left(\psi_{\mathrm{i}} \phi_{\mathrm{i}} \varphi_{\mathrm{i}} \sigma_{\mathrm{i}}^{2}\right), \tau_{\mathrm{i}}{ }^{\prime}=\left(\mathrm{d}_{\mathrm{i}} \mathrm{v}_{\mathrm{i}} \mathrm{s}_{\mathrm{i}} \mathrm{y}_{\mathrm{i}}^{2}\right), \gamma$ is the vector of coefficients and $\mathrm{A}_{1}, \ldots, \mathrm{~A}_{\mathrm{q}}$ and $\mathrm{B}_{0}, \ldots$, $B_{p}$ are matrices of coefficients of each one of the stochastic processes of the system.

The general formulation of the complete model can be written as follows.

## - Observation equation:

$$
\left[\begin{array}{c}
x_{i}  \tag{2.14}\\
v_{i} \\
s_{i} \\
y_{i}
\end{array}\right]=\left[\begin{array}{cccc}
\psi_{i} & 0 & 0 & 0 \\
0 & \phi_{i} & 0 & 0 \\
0 & 0 & \varphi_{i} & 0 \\
0 & 0 & 0 & \sigma_{i}
\end{array}\right] \cdot\left[\begin{array}{c}
\varepsilon_{i} \\
\eta_{i} \\
\varpi_{i} \\
\zeta_{i}
\end{array}\right]
$$

Where, $\varepsilon_{i}, \eta_{\mathrm{i}} \mathrm{e} \omega_{\mathrm{i}} \sim \exp (1) \mathrm{e} \zeta_{\mathrm{i}} \sim \mathrm{N}(0,1)$.

- State equation:

$$
\begin{align*}
& {\left[\begin{array}{l}
\psi_{i} \\
\phi_{i} \\
\varphi_{i} \\
\sigma_{i}^{2}
\end{array}\right]=\left[\begin{array}{l}
a_{0} \\
b_{0} \\
c_{0} \\
d_{0}
\end{array}\right]+\sum_{l=1}^{q}\left[\begin{array}{llll}
a_{1}^{(l)} & a_{2}^{(l)} & a_{3}^{(l)} & a_{4}^{(l)} \\
b_{1}^{(l)} & b_{2}^{(l)} & b_{3}^{(l)} & b_{4}^{(l)} \\
c_{1}^{(l)} & c_{2}^{(l)} & c_{3}^{(l)} & c_{4}^{(l)} \\
d_{1}^{(l)} & d_{2}^{(l)} & d_{3}^{(l)} & d_{4}^{(l)}
\end{array}\right] \ln \left[\begin{array}{c}
\psi_{i-l} \\
\phi_{i-l} \\
\varphi_{i-l} \\
\sigma_{i-l}^{2}
\end{array}\right]}  \tag{2.15}\\
& +\left[\begin{array}{cccc}
0 & 0 & 0 & 0 \\
b_{5} & 0 & 0 & 0 \\
c_{5} & c_{6} & 0 & 0 \\
d_{5} & d_{6} & d_{7} & 0
\end{array}\right] \ln \left[\begin{array}{c}
x_{i} \\
v_{i} \\
s_{i} \\
y_{i}^{2}
\end{array}\right]+\sum_{m=1}^{p}\left[\begin{array}{llll}
a_{5}^{(m)} & a_{6}^{(m)} & a_{7}^{(m)} & a_{8}^{(m)} \\
b_{6}^{(m)} & b_{7}^{(m)} & b_{8}^{(m)} & b_{9}^{(m)} \\
c_{7}^{(m)} & c_{8}^{(m)} & c_{9}^{(m)} & c_{10}^{(m)} \\
d_{11}^{(m)} & d_{12}^{(m)} & d_{13}^{(m)} & d_{14}^{(m)}
\end{array}\right] \ln \left[\begin{array}{c}
x_{i-m} \\
v_{i-m} \\
s_{i-m} \\
y_{i-m}^{2}
\end{array}\right]
\end{align*}
$$

The system presents an iterative dynamic due to the fact that matrix $\mathrm{B}_{0}$ is a lower triangular matrix with null main diagonal elements.

Based on equation (2.15), we can infer about the structure of the system by testing different constraints. Three structures are suggested:

- Complete model: the structure of coefficients matrices is exactly as shown in equation 2.15. In that case, the conditional mean and contemporaneous and lagged variables can influence the dynamic of the system. The causality relation is explicitly modeled.
- Variation-free: the matrices $\mathrm{A}_{1}, \mathrm{~A}_{2}, \ldots$ and $\mathrm{A}_{\mathrm{q}}$ in 2.15 are diagonal. The conditional mean of each variable cannot influence the others.
- Individual: matrix $B_{0}$ is null and the other matrices in 2.15 are diagonal (constraint model - no causality relation). Here, the conditional mean of each variable evolves based on its own lagged values and the ones of the original variable. The individual formulation is obtained (ACD, ACV, ACS and GARCH).

Equation 2.18 presents the joint likelihood function:

$$
\begin{align*}
& L\left(x, v, s, y \mid I_{N}\right)= \\
& \prod_{i=1}^{N}\left[\frac{1}{\psi_{i}} \exp \left(-\frac{x_{i}}{\psi_{i}}\right) \frac{1}{\phi_{i}} \exp \left(-\frac{v_{i}}{\phi_{i}}\right) \frac{1}{\varphi_{i}} \exp \left(-\frac{s_{i}}{\varphi_{i}}\right) \frac{1}{\sqrt{2 \pi \sigma^{2}}} \exp \left(-\frac{y_{i}^{2}}{2 \sigma_{i}^{2}}\right)\right] \tag{2.16}
\end{align*}
$$

Where, the conditional means $\psi_{\mathrm{i}}, \phi_{\mathrm{i}}, \varphi_{\mathrm{i}}$ and $\sigma_{\mathrm{i}}^{2}$ are defined by equation 2.13.

## 3 Intra-day Pattern Adjustment

Some of the variables being analyzed may present an intra-day pattern. As proposed by Engle and Russell (1998), all periodic or cyclic behavior should be removed before model estimation in order to avoid spurious autocorrelation. We define,

$$
\begin{equation*}
x_{i}^{*}=x_{i} / \lambda\left(x_{i}, t_{i}\right) \quad v_{i}^{*}=v_{i} / \lambda\left(v_{i}, t_{i}\right) \quad s_{i}^{*}=s_{i} / \lambda\left(s_{i}, t_{i}\right) \quad y_{i}^{2^{*}}=y_{i}^{2} / \lambda\left(y_{i}^{2}, t_{i}\right) \tag{3.1}
\end{equation*}
$$

Where, $\mathrm{x}_{\mathrm{i}}{ }^{*}, \mathrm{v}_{\mathrm{i}}{ }^{*}, \mathrm{~s}_{\mathrm{i}}{ }^{*}, \mathrm{y}_{\mathrm{i}}{ }^{2 *}$ are, respectively, the deseasonalized series of duration, volume, spread and volatility.

In this paper we use a natural cubic spline for each variable considered in the system equation. In order to estimate the deterministic function that will represent the different seasonal patterns, the time interval between the opening and closing of trading days was divided into equally spaced intervals of one hour. In order to increase the flexibility, one extra node was added at the end of the trading day.

Thus, the intra-day seasonal pattern is defined through the following equation:

$$
\begin{equation*}
\lambda\left(t_{i-1}\right)=\sum_{j=1}^{K} I_{j}\left[c_{j}+d_{1, j}\left(t_{i-1}-k_{j-1}\right)+d_{2, j}\left(t_{i-1}-k_{j-1}\right)^{2}+d_{3, j}\left(t_{i-1}-k_{j-1}\right)^{3}\right] \tag{3.7}
\end{equation*}
$$

Where,
K - number of segments;
I - variable that represents the j -th segment of the spline $\left(\mathrm{I}_{\mathrm{j}}=1\right.$ if $\mathrm{k}_{\mathrm{j}-1}<\mathrm{t}_{\mathrm{i}-\mathrm{j}}<\mathrm{k}_{\mathrm{j}}$ and $\mathrm{I}_{\mathrm{j}}=0$, on the contrary).

## 4 Estimation Process

Two different optimization algorithms were used: Quadratic Sequential Programming (SQP) for the intra-day seasonal pattern determination and the Nelder-Mead Simplex Method to system's parameters estimation, because of the discontinuities of the log-likelihood function.

### 4.1 Quadratic Sequential Programming:

Based on the study of Biggs (1975), Han (1977) and Powell (1978), the method should be understood as a proxy of Newton's method (nonlinear programming without constraints), for constraint problem.

Algorithm: In each iteration, the objective function Hessian is calculated through BFGS method. The Hessian is then applied in a quadratic programming sub-problem. The solution is taken as reference to the subsequent liner search procedure, initializing a new iteration.

### 4.2 Nelder-Mead Simplex Method:

Introduced by Nelder e Mead (1965), the main idea of the method is the determination of the minimum value point of a certain N variables function through the use of a $\mathrm{N}+1$ vertices simplex.

In this method, the simplex adapts itself to the local landscape, elongating down long inclined planes, changing direction on encountering a valley at an angle, and contracting in the neighborhood of a minimum.

The criterion for stopping the process has been chosen keeping in mind the application in statistical problem involving the maximization of the likelihood function in which the unknown parameters enter nonlinearly.

Algorithm: Consider the minimization problem of a function of N variable, without constraints. Let $\mathrm{P}_{0}, \mathrm{P}_{1}, \ldots, \mathrm{P}_{\mathrm{N}}$ as the $\mathrm{N}+1$ points of the N -dimensional space defining the current simplex. Define $y_{i}$ as the function value at $P_{i}, y_{h}=\max \left(y_{i}\right)$ for $i=0, \ldots, N$ and $y_{l}=\min \left(y_{i}\right)$ for $i=$ $0, \ldots, \mathrm{~N}$.

Additionally, let $P_{\text {hat }}$ as being the centroid of the region defined by $P_{i}$ 's, where $i$ is different from $h$ and $\left[P_{i} P_{j}\right]$ is the distance from $P_{i}$ to $P_{j}$. For each stage in the process $P_{h}$ is replaced by a new point; three operations are used - reflection, contraction and expansion.

The reflection of $\mathrm{P}_{\mathrm{h}}$ is denoted by $\mathrm{P}^{*}$ and its coordinates are defined by:

$$
\begin{equation*}
P^{*}=(1+\alpha) . P_{h a t}-\alpha \cdot P_{h} \tag{4.2.1}
\end{equation*}
$$

Where, $\alpha$ is a positive constant (reflection coefficient).
Thus, the point $P^{*}$ is on the line joining $P_{h}$ and $P_{\text {hat }}$, on the far side of $P_{\text {hat }}$ from $P_{h}$ with [ $\left.\mathrm{P}^{*} \mathrm{P}_{\text {hat }}\right]=\alpha .\left[\mathrm{P}_{\mathrm{h}} \mathrm{P}_{\text {hat }}\right.$ ]. If $\mathrm{y}_{\mathrm{l}}<\mathrm{y}^{*}<\mathrm{y}_{\mathrm{h}}$, so $\mathrm{P}_{\mathrm{h}}$ will be replaced by $\mathrm{P}^{*}$ and a new simplex is generated.

If $\mathrm{y}^{*}<\mathrm{y}_{\mathrm{l}}$, i.e. if reflection has produced a new minimum point, so, $\mathrm{P}^{*}$ is expanded to $\mathrm{P}^{* *}$ by the following relation:

$$
\begin{equation*}
P^{* *}=\gamma \cdot P^{*}+(1-\gamma) \cdot P_{h a t} \tag{4.2.2}
\end{equation*}
$$

The expansion coefficient $\gamma$ (greater than unity), corresponds to the ratio between the distances [ $\mathrm{P}^{* *} \mathrm{P}_{\text {hat }}$ ] and [ $\mathrm{P}^{*} \mathrm{P}_{\text {hat }}$. If $\mathrm{y}^{* *}<\mathrm{y}_{\mathrm{l}}, \mathrm{P}_{\mathrm{h}}$ is replaced by $\mathrm{P}^{* *}$ and the process is restarted. But, if $y^{* *}>y_{l}$, then the reflection has failed and, before restarting the process, $P_{h}$ must be replaced by $\mathrm{P}^{*}$.

If, on reflecting $P$ to $P^{*}, y^{*}>y_{i}$, for all i different of $h$, so it must be defined a new $P_{h}$ as being the old $\mathrm{P}_{\mathrm{h}}$ or $\mathrm{P}^{*}$ (whichever has the lower y value) and form:

$$
\begin{equation*}
P^{* *}=\beta \cdot P_{h}+(1-\beta) \cdot P_{h a t} \tag{4.2.3}
\end{equation*}
$$

The contraction coefficient $\beta$ lies between 0 and 1 and is the ratio between $\left[\mathrm{P}^{* *} \mathrm{P}_{\text {hat }}\right]$ and [ $\mathrm{P} \mathrm{P}_{\text {hat }}$ ]. In that way, $\mathrm{P}_{\mathrm{h}}$ is replaced by $\mathrm{P}^{* *}$, unless $\mathrm{y}^{* *}>\min \left(\mathrm{y}_{\mathrm{h}}, \mathrm{y}^{* *}\right)$. If it occurs, the points $\mathrm{P}_{\mathrm{i}}$ 's are replaced by $\left(\mathrm{P}_{\mathrm{i}}+\mathrm{P}_{\mathrm{i}}\right) / 2$ and the process is restarted.

All the process finishes when the diameter of the simplex points is smaller than a prespecified value.

Since the Nelder-Mead Method does not use the Hessian when solving the optimization problem, in order to estimate Fisher Information Matrix, it's being proposed the use of Spendley's procedure (1962). The method consists on adjusting a quadratic surface on the region composed by the $\mathrm{N}+1$ simplex vertices, in the neighborhood of the optimal solution.

## 5 Verifying the estimation algorithm

In order to test the identification power of the proposed method, a Monte-Carlo Simulation was carried out. Here, the joint model, as described in equations 2.14 and 2.15 , is simulated - EMACM(2,2). We've generated 20 realizations of the process with 1000 observations each. The parameters are estimated by maximizing the likelihood function (2.16).

Through the impulse-response function analysis the real and estimated processes are compared. The figures bellow present the main results (red dashed line - estimated impulseresponse function values, red line - the mean of estimated values and blue line - impulseresponse of the real data generate process - DGP).

- Duration:

Figure 2 - Duration responses due to impulse in duration, volume, spread and volatility

- Volume:

Figure 3 - Volume responses due to impulse in duration, volume, spread and volatility

- Spread:

Figure 4 - Spread responses due to impulse in duration, volume, spread and volatility

## - Volatility:

Figure 5 - Volatility responses due to impulse in duration, volume, spread and volatility

Based on the impulse-response function, we've found that the behavior of the estimated processes is close to the real one. This exercise shows that the estimation procedure presents a good identification power.

## 6 Empirical Analyses

### 6.1 Data Base:

The data used in the empirical analysis was built by Joel Hasbrouck e NYSE - Trades, Orders Reports and Quotes (TORQ). The data reflect the trades of IBM stocks, occurred between November $1^{\text {st }}, 1990$ and December $3^{\text {rd }}, 1991$.

The data comprehend all the relevant information embedded in financial transactions buys or sells (i.e., bid price, ask price, transaction price, time and volume) registered during regular financial market time - 9:30 AM - 4:00 PM (after-market is not considered).

Since the study will focus on the modeling of tick-by-tick data (price change), some changes were implemented in the original data.

## - Duration:

- If the price of transaction " i " is equal to the price of transaction " $\mathrm{i}-1$ ", the durations are added;
- If a certain transaction presents duration equal to zero, it's removed.
- Volume:
- If the price of transaction " i " is equal to the price of transaction " $\mathrm{i}-1$ ", the volume "i" will be the mean of the volumes of both transactions.
- Spread:
- If the price of transaction " i " is equal to the price of transaction " $\mathrm{i}-1$ ", spread " i " will be the mean of the spreads " $i$ " and " $i-1$ " weighted by the volumes of such transactions.

Other relevant changes and considerations:

- November 23rd, 1990: was removed from the data base, due to an interruption of approximately one hour and fifteen minutes in the transactions.
- The tick-by-tick series take the unity value of the tick as reference (US\$ 0.125);
- The transaction occurred during the first twenty minutes of trading day were not considered for estimation purposes (9:30 AM - 9:50 AM), because of opening postponing problems and "first trades" effects;
- For each day, the conditional mean of each one of the variables of the system (deseasonalized series) will be taken as the mean of the respective values observed between 9:50 AM and 10:00 AM (if there are no observations, the conditional mean is taken as one).

### 6.2 Empirical Tests:

The data set used has a total of 5806 different financial transactions. The first phase of the experiment corresponds to the estimation ${ }^{1}$ of an $\operatorname{EMACM}(2,2)$, as described by equation 2.13. Here, the three structures are considered (tables I, II and III, in appendix, bring the results).

As already mentioned, before starting the estimation process the variable must be deseasonalized. Thus, following section 3, the off-line determination of the intra-day seasonal pattern is obtained. Figure 6 shows the results for each trading variable.

Figure 6 - Intra-day seasonal pattern
Regarding the seasonal pattern of trading variables, as pointed by Engle and Russell (1998), the highest intensity (lower durations) is observed close to the opening and closing of the trading days. Additionally, we can observe that bid-ask spread and price volatility increase, as a consequence of that fact.

Regarding volume seasonal pattern, the highest values are observed next to the opening, what can be explained by the fact that new information is not included in asset prices.

After removing seasonal effects, the system can be estimated through the use of NelderMead Simplex Method. Following, the main results are presented and the three formulations proposed in that article are tested and compared.

[^0]
## - Complete model:

- ACF
- Duration: figure 7 shows that the model captures the linear dependence observed in original data.

Figure 7 - ACF of duration (residuals x observations)

- Volume: figure 8 shows that both the original data and the residuals don't present linear dependence. However, the hypothesis of null parameters in volume process has been rejected for all of them.

Figure 8 - ACF of volume (residuals x observations)

- Spread: based on figure 9 , we see that the model reduces the linear dependence observed in bid-ask spreads.

Figure 9 - ACF of spread (residuals $x$ observations)

- Volatility: in figure 10, we observe a strong linear dependence (first lag) in instantaneous volatility (squared of instantaneous return $-\mathrm{y}^{2}$ ), what is reduced but not completely captured by the model.

Figure 10 - ACF of volatility (residuals x observations)

- Real x Forecasted: figure 11 presents the trading variables plotted against the one-stepahead forecasts.

Figure 11 - Real x forecasted analysis data - model complete

- Complete $\mathbf{x}$ variation-free $\mathbf{x}$ individual: table 1 presents the results of Ljung-Box test. The test is based on the autocorrelation plot. However, instead of testing randomness at each distinct lag, it tests the "overall" randomness based on a number of lags. The null hypothesis states that there are no linear dependence in data series.

|  |  | Accept $\mathrm{HO}(95 \%)$ | P-Value | Ljung-Box | Critical Value |
| :---: | :---: | :---: | :---: | :---: | :---: |
| n$\stackrel{0}{0}$0000 | Duration | Reject | 0,00\% | 442,25 | 25,00 |
|  | Volume | Reject | 1,95\% | 28,34 | 25,00 |
|  | Spread | Reject | 0,00\% | 774,45 | 25,00 |
|  | Volatility | Reject | 0,00\% | 1486,72 | 25,00 |

Table 1 - Linear dependency analysis (complete, variation-free and individual)
Based on the results obtained, it could be noticed that the proposed formulation deals quite satisfactory with the linear dependence observed in the original data. However, as seen in figure 11, there is an excessive dispersion in the residuals of all series being considered, it's probably due to the non-linearity existent in these data as observed by Engle and Russell (1998), Fernandes and Gramming (2001) and Zhang, Russell and Tsay (2001).

The constraint formulation (variation-free) has obtained a better performance when considering in-sample tracking.

In order to test the validity of constrains on the complete formulation, we use the likelihood ratio test. The null hypothesis regards the validity of the constraint formulation against the less restricted ones. Table 2 presents the results.

## - Likelihood Ratio Test:

|  | Accept $\mathbf{H}_{0}$ (95\%) | P-Value | Likelihood Ratio Test | Critical Value (95\%) |
| :--- | :---: | ---: | ---: | ---: |
| Complete $\times$ Variation-Free | Accept | $70,06 \%$ | 27,11 | 36,42 |
| Complete $\times$ Individual | Reject | $0,00 \%$ | 1123,87 | 72,15 |
| Variation-Free $\times$ Individual | Reject | $0,00 \%$ | 1096,76 | 43,77 |

Table 2 - Likelihood ratio test results
Considering the results of table 2 , the system seems to be variation-free, as proposed by Manganelli. That hypothesis is strongly accepted ( p -value $=70,06 \%$ ). The hypothesis tests that consider individual formulation strongly reject the validity of independent dynamics in trading variables.

## 7 Conclusion and Final Comments

The EMACM is a framework to analyze high-frequency data, that allows expected duration, volume, bid-ask spread and volatility to vary according to a nonlinear function of their own lagged values. Here the exponential transformation is applied in order to guarantee the nonnegativity of the variables under study. The model is estimated through the maximization of the joint likelihood function (complete formulation), using a non-linear unconstraint optimization algorithm (Nelder-Mead).

The estimation process was tested through a Monte-Carlo experiment. The impulseresponse function based on estimated parameters was compared to the values obtained through the use of the original ones.

Regarding the intra-day estimated pattern, some facts brought-up by microstructure theory could be observed:

- Highest intensity (lower durations) were observed close to the opening and closing of trading days;
- For lower duration values: bid-ask spread and instantaneous volatility increase;
- Highest volumes are observed next to the opening of transaction days - what can be explained by the fact that new information accumulated after trading regular time wouldn't be included in asset prices.

In relation to the adoption of constrains on the complete formulation (different structures), a Likelihood Ratio Test was carried-out. The results point to the acceptance of the variation-free formulation, as suggested by Manganelli. Here, the hypothesis of no causality among trading variables is strongly rejected.

Generally, the new model was successful when dealing with the linear dependence in data. On the other hand, it was observed an excess of dispersion in data, probably due to the nonlinearities - first identified by Engle and Russel (1998), what was not captured.
