*Abstract:*

*Diba and Grossman (1988) and Hamilton and Whiteman (1985) recommended unit root tests for rational bubbles. They argued that if stock prices are not more explosive than dividends, then it can be concluded that rational bubbles are not present.*

*Evans (1991) demonstrated that these tests will fail to detect the class of rational bubbles which collapse periodically. When such bubbles are present, stock prices will not appear to be more explosive than the dividends on the basis of these tests, even though the bubbles are substantial in magnitude and volatility.*

---

<sup>1</sup> The authors would like to thank Professor James Hamilton and Professor Anil K. Bera for their comments and recommendations. Any remaining errors are the responsibilities of the authors.

*Hall et al. (1999) show that the power of unit root test can be improved substantially when the underlying process of the sample observations is allowed to follow a first-order Markov process.*

*Our paper applies unit root tests to the property prices of Hong Kong and Seoul, allowing for the data generating process to follow a three states Markov chain. The null hypothesis of unit root is tested against the explosive bubble or stable alternative. Simulation studies are used to generate the critical values for the one-sided test.*

*The time series used in the tests are the monthly price and rent indices of Seoul's housing (1986:1 to 2003:6) and Hong Kong's retail premise (1980:12 to 2003:1). The investigations show that only one state appears to be highly likely in all series under investigation and the switching unit root procedure failed to find explosive bubbles in both prices.*

## **I. Introduction**

A rational bubble reflects a self-confirming belief that the price of an asset depends on a variable, or a combination of variables, that is intrinsically irrelevant, or on truly relevant variables in a way that involves parameters that are not part of market fundamentals. A basic difficulty in testing for rational bubbles is that the contribution to asset prices by hypothetical rational bubbles would not be directly distinguishable from that by an unobservable market fundamental.

Diba and Grossman (1988) implements stationarity tests for the existence of explosive rational bubbles without precluding the possible effect of unobservable market fundamentals. They argued that if the first differences of the unobservable variables and the first differences of dividends are stationary in the mean, and if rational bubbles do not exist, then the first differences of stock prices are stationary; or if the levels of the unobservable variables and the first differences of dividends are stationary, and if rational bubbles do not exist, then stock prices and dividends are cointegrated of order (1,1). If, however, stock prices contain a rational bubble, differencing stock prices a finite number of times would not yield a stationary process. Although the finding that the first differences of stock prices are nonstationary, or that stock prices and dividends are not cointegrated do not automatically establish the existence of rational bubbles due to the unobservable variable, the converse inference is however possible. That is, evidence that the first differences of stock prices have a stationary mean or evidence that stock prices are cointegrated with dividends would be evidence against the existence of rational bubbles.

Evans (1991) shows that the stationarity tests, suggested by Diba and Grossman (1984, 1988) and Hamilton and Whiteman (1985), is in fact unable to detect the periodically collapsing bubbles. He demonstrates, using simulations, that when such bubbles are present, stock prices will not appear to be more explosive than dividends on the basis of these tests, even though the bubbles are substantial in magnitude and volatility.

Hall, Psaradakis and Sola (1999) argue that testing for collapsing bubbles is essentially one of identifying the expanding phase from the collapsing phases of the bubbles. They proposed a generalized ADF unit root test, which allows for the data generating process (DGP) to switch parameters in different states. They concluded that, unlike standard unit root tests, which have little power to detect periodically collapsing bubbles, their switching ADF tests are able to give sensible inferences about the DGPs.

This paper intends to apply the switching ADF test, suggested by Hall, Psaradakis and Sola (1999), to the property prices in Hong Kong and Seoul. The remaining paper consists of three sections: the first introduces the literature of unit root tests for rational bubbles; the second give our estimation and test results; and the last section concludes the paper with discussions on our findings.

## II. Review

### 2.1 Diba and Grossman's (1988) tests

In their stationairy test, Diba and Grossman assume that the data generating process can be described by the model consists of equation (2.1.1) to (2.1.5).

$$P_t = (1 + r)^{-1} E_t(P_{t+1} + \alpha d_{t+1} + u_{t+1}) \quad (2.1.1)$$

where  $P_t$ : the real stock price at time t;

$r$  : the constant real discount rate.

$E_t$ : the conditional expectations operator;

$\alpha$ : a positive constant that valuates expected dividends relative to expected capital gains.

$d_{t+1}$ : the real dividends payment between time  $t$  and  $t+1$ ;

$u_{t+1}$ : a variable that market participants either observe or construct, but that the researcher does not observe.

The fundamental solution for equation (2.1.1) is

$$F_t = \sum_{j=1}^{\infty} (1+r)^{-j} E_t [\alpha d_{t+j} + u_{t+j}] \quad (2.1.2)$$

Whereas the general solution would include a rational bubble component,  $B_t$

$$P_t = F_t + B_t \quad (2.1.3)$$

and  $B_t$  satisfy

$$B_{t+1} = (1+r)B_t + z_{t+1} \quad (2.1.4)$$

The random variable  $z_{t+1}$  is an innovation comprising new information available at date  $t+1$ . This information can be intrinsically irrelevant, or it can be related to relevant variables through parameters that are not present in  $F_{t+1}$ . The expected future values of  $z_{t+1}$  are always zero

$$E_{t-j} z_{t+1} = 0 \text{ for all } j \geq 0 \quad (2.1.5)$$

Assume that  $d_t$  is nonstationary in levels, but the first differences of  $d_t$  and  $u_t$  are stationary. Then  $P_t$  will be nonstationary in levels but stationary in first difference, when rational bubbles do not exist. However, when rational bubbles are in presence, differencing  $P_t$  a finite number of times would not yield a stationary process, since  $B_t$  would have the generating process

$$[1 - (1 + r)L](1 - L)B_t = (1 - L)z_t \quad (2.1.6)$$

which is neither stationary nor invertible.<sup>2</sup>

By examining the sample autocorrelations and by applying the standard ADF tests, Diba and Grossman concluded that both real stock prices and dividends are nonstationary in levels but stationary in first differences. They also conducted a cointegration test on the stock prices and dividends. Rearranging equation (2.1.2) and substitute it into equation (2.1.3) yields

$$P_t - \alpha r^{-1} d_t = B_t + \alpha r^{-1} \left[ \sum_{j=1}^{\infty} (1 + r)^{1-j} E_t \Delta d_{t+j} \right] + \sum_{j=1}^{\infty} (1 + r)^{-j} E_t u_{t+j} \quad (2.1.7)$$

If  $u_t$  is stationary in levels, and  $d_t$  is stationary in first difference, and if  $B_t$  equals zero, then  $P_t$  and  $d_t$  are cointegrated of order (1,1), with cointegrating vector  $(1, -\alpha r^{-1})$ . Their tests, however, show mixed results.

The lack of cointegration in stock prices and dividends could be due to the nonstationarity of the unobservable variable,  $u_t$ . They explore this possibility by using the following equation, implied by equation (2.1.1),

$$P_{t+1} + \alpha d_{t+1} - (1 + r)P_t = e_{t+1} - u_{t+1}$$

where  $e_{t+1}$  is the expectation error. That is

$$e_{t+1} = P_{t+1} + \alpha d_{t+1} + u_{t+1} - E_t(P_{t+1} + \alpha d_{t+1} + u_{t+1})$$

---

<sup>2</sup> A similar demonstration is given by Evans (1991) in page 923.

The assumption of rational expectation implies that  $e_{t+1}$  are not serially correlated. Thus, if  $P_{t+1} + \alpha d_{t+1}$  and  $P_t$  are cointegrated of order (1,1) with cointegrating vector (1, -(1+r)), then  $u_t$  is stationary in level. Their tests suggests that the null hypothesis of no cointegration can be rejected.

The conclusion that  $\Delta d_{t+1}$ ,  $\Delta P_{t+1}$  and  $(P_{t+1} + \alpha d_{t+1} - (1+r)P_t)$  are all stationary would imply that  $P_t - \alpha r^{-1}d_t$  is stationary. Therefore, they lamented that the lack of cointegration between  $P_t$  and  $d_t$  is puzzling. Given these problems, they appealed to an alternative, the Bhargava Tests, to further investigate the stationarity properties of  $P_t - \alpha r^{-1}d_t$ . Bhargava tests yield the most powerful invariant tests of random-walk hypothesis against the one-sided stationary and explosive alternatives. The existence of explosive rational bubbles would imply that  $P_t - \alpha r^{-1}d_t$  has an explosive, rather than a unit, root. The Bhargava tests strongly suggest that stock prices and dividends are cointegrated, and, thus, are consistent with the finding that any unobservable fundamental variables, and the first differences of stock prices and dividends are all stationary.

To verify that their tests would detect explosive bubbles if they were present, they applied the same tests to simulated time-series. Their findings are positive. Hence they concluded in their paper that explosive rational bubbles do not exist in stock prices.

## 2.2 Evan's (1991) Criticism

Evans argued that, when applied to periodically collapsing rational bubbles, the test procedures suggested by Diba and Grossman can, with high probability, incorrectly lead to the conclusion that these bubbles are not present.

Suppose that the data generation process for stock prices can be adequately represented by the standard present value model given in equation (2.2.1) to (2.2.11)

$$P_t = (1+r)^{-1} E_t(P_{t+1} + d_{t+1}), \quad 0 < (1+r)^{-1} < 1 \quad (2.2.1)$$

variables in the equation have the same interpretations as in equation (2.1.1). This representation ignores the possibility of unobservable fundamentals, since they are not consequential to the point to be made.

The fundamental solution to (2.2.1) is

$$F_t = \sum_{j=1}^{\infty} (1+r)^{-j} E_t[d_{t+j}] \quad (2.2.2)$$

and the general solution is

$$P_t = F_t + B_t \quad (2.2.3)$$

Where  $B_t$ , the rational bubble, satisfies

$$E_t B_{t+1} = (1+r)B_t \quad (2.2.4)$$

If the first difference the dividends series is a stationary ARMA process and if there are no bubbles, then it can be shown that the first difference of the price series is also a stationary ARMA process, and that  $P_t$  and  $d_t$  are cointegrated with cointegrating vector  $(1, -r^{-1})$ . If, instead,  $\Delta d_{t+1}$  is stationary but  $B_t$  is not absent, then for some  $C_t$

$$E_t F_t \rightarrow C_t + \lambda j \quad \text{as } j \rightarrow \infty \quad (2.2.5)$$

where  $\lambda = E(\Delta F_t)$

But

$$E_t B_{t+j} = (1+r)^j B_t \quad (2.2.6)$$

That is the conditional expectations of the future fundamental price grows linearly in the forecast horizon  $j$ , reflecting the unit root in the process, whereas the conditional expectations of future bubbles contains the root  $(1+r)>1$ . If  $B_t$  is nonzero, as  $j$  increases, the conditional expectation  $P_{t+j}$  will eventually be dominated by the explosive root  $(1+r)$ , if a bubble is present. Furthermore, differencing the price will not render the process stationary, since

$$\lim_{j \rightarrow \infty} E_t \Delta F_{t+j} = E(\Delta F_t), \text{ a constant} \quad (2.2.7)$$

but

$$E_t \Delta B_{t+j} = r(1+r)^{j-1} B_t, \text{ which is explosive if } B_t \neq 0 \quad (2.2.8)$$

Hence, the conditional expectation of  $\Delta P_{t+j}$  will be stable if the bubble is absent, but explosive otherwise.

These considerations are the motivations behind the unit root and cointegration tests by Diba and Grossman (1988).

Evans, however, demonstrated that if the bubbles collapse periodically, such tests have very little power in detecting the presence of bubbles.

Consider the class of rational bubbles that are always positive but collapse periodically

$$B_{t+1} = (1+r)B_t u_{t+1}, \quad B_t \leq \alpha \quad (2.2.9)$$

$$B_{t+1} = [\delta + \pi^{-1}(1+r)\theta_{t+1}(B_t - (1+r)^{-1}\delta)]u_{t+1}, \quad \text{if } B_t > \alpha \quad (2.2.10)$$

where  $\alpha$  and  $\delta$  are positive parameters with  $0 < \delta < (1+r)\alpha$ , and

$u_t$ : an exogenous i.i.d positive random variable, with  $E_t u_{t+1} = 1$ .

$\theta_{t+1}$ : an exogenous i.i.d Bernoulli process independent of  $u$ , with

$$\Pr(\theta_{t+1} = 1) = \pi$$

$$\Pr(\theta_{t+1} = 0) = 1 - \pi, \quad 0 < \pi \leq 1$$

Assume

$$u_t = \exp\left(y_t - \frac{\tau^2}{2}\right), \quad y_t \text{ iid}, N(0, \tau^2) \quad (2.2.11)$$

The frequency with which bubbles erupt, the average length of time a bubble expands, and the magnitude of bubble are affected by the process parameters  $\alpha$ ,  $\delta$  and  $\pi$ .

When the Bhargava test is applied to the 200 simulated samples of size 100, generated by DGPs described by equations (2.2.1) to (2.2.11), Evans found that the results of tests depend critically on  $\pi$ , *the probability per period that the bubble does not collapse*.

When  $\pi$  is close to one, the tests results are close to those obtained by Diba and Grossman. However, for  $\pi \leq 0.95$ , quite different results are obtained. In fact, when  $\pi \leq 0.75$ , more than 90% of the simulation reject the null hypothesis of a unit root in favor of stable alternatives for both N1 and N2 statistics. These results appear to be robust to moderate changes in the other model parameters.

Evans explains that the maintained hypothesis for the Bhargava test is a first order autoregressive process. When  $\pi$  is close to one, the process for (2.2.10) converges to (2.2.9). But when  $\pi \leq 1$ , the bubble process in (2.2.10) is a complex nonlinear process, which falls outside the maintained hypothesis. Thus, unless  $\pi$  is close to one, the pattern of periodic collapse generated by (2.2.10) looks more like a stable AR(1) process other than an explosive one, despite of the explosive root in the conditional expectation of the bubble sequence.

Evans also applied the Dickey-Fuller unit root tests and cointegration tests to the simulated stock prices and dividends, assuming

$$d_t = \mu + d_{t-1} + \varepsilon_t \quad \varepsilon_t \sim iid, N(0, \sigma_\varepsilon^2) \quad (2.2.12)$$

The results clearly show that the DF  $\phi_3$  statistic is unable to find the bubble when it is present. The cointegration tests, using the Durbin-Watson statistic and the Engle and Granger (1987)  $\xi_2$  and  $\xi_3$  statistics also incorrectly indicate the absence of bubbles in the majority of simulations.

In summary, periodically collapsing bubbles are not detected by standard unit root and cointegration tests.

### 2.3 Markov-Switching Unit Root Test

Hall, Psaradakis and Sola (1999) argued that, when rational bubbles exist, the dynamics of asset prices are driven by the dynamics of the bubbles. If the bubbles collapse periodically, the values taken by the parameters of the price generating process in the bubble expansion state will differ from that in the bubble collapsing state. That is the model governing the price behavior experiences structural break. When the model has structural breaks, ADF tests have little power. In such cases, allowing for the ADF regression parameters to take on different values in different states will improve the power of the tests. In particular, the authors suggested to make use of the class of dynamic Markov-switching models explored in Hamilton (1989, 1990), and base the unit root test on the following regression model

$$\Delta y_t = \mu_0(1-s_t) + \mu_1 s_t + [\phi_0(1-s_t) + \phi_1 s_t] y_{t-1} + \sum_{j=1}^k [\psi_{0j}(1-s_t) + \psi_{1j} s_t] \Delta y_{t-j} + \sigma_e e_t \quad (2.3.1)$$

where  $e_t \text{ iid}, N(0,1)$

and  $s_t$  is a state variable independent of  $e_m$  for all  $t$  and  $m$ , and follows first-order Markov chain on the state space  $\{0,1\}$  with transition probabilities

$$\begin{aligned} \Pr(S_t = 1 | S_{t-1} = 1) &= p \\ \Pr(S_t = 0 | S_{t-1} = 1) &= 1 - p \\ \Pr(S_t = 0 | S_{t-1} = 0) &= q \\ \Pr(S_t = 1 | S_{t-1} = 0) &= 1 - q \end{aligned} \quad (2.3.2)$$

The coefficient on  $y_{t-1}$  provides the basis for testing. For example, existence of an explosive rational bubble in prices is consistent with  $\phi_0 > 0$  or  $\phi_1 > 0$ . On the other hand, when  $\phi_0 = \phi_1 = 0$  for both price and dividends, there is no rational bubble. A test of the unit root null hypothesis may be based on the asymptotic t-ratios associated with the ML estimates of  $\phi_0$  or  $\phi_1$ .

The authors conducted a simulation study based on 500 independent realizations of  $\{P_t\}$  from DGPs identical to those used by Evans (1991). Two alternative assumptions about the generating mechanism of real dividends are used, namely,

$$d_t = \mu + d_{t-1} + \varepsilon_t \quad (2.3.3)$$

and

$$\ln d_t = \mu + \ln d_{t-1} + \varepsilon_t \quad (2.3.4)$$

where

$$\varepsilon_t \xrightarrow{d} iid, N(0, \sigma_\varepsilon^2)$$

Their results show that, unlike the conventional ADF test, Markov-switching ADF procedure has considerable power to detect the presence of bubbles in  $\{P_t\}$ . They cautioned, however, these results do not imply that switching ADF tests would successfully detect all types of periodically collapsing bubbles. For example, if the contribution of the bubble to the volatility of the prices is not substantial or the probability of the bubble collapse  $1 - \pi$  is relatively large, it would be difficult for any tests to confirm the presence of the bubble.

The authors then went on to apply the test procedure to investigate the integration properties of consumer prices in Argentina. As argued in Diba and Grossman, whether or not the nonstationarity in prices reflects a rational bubble depends on the time-series properties of the economic fundamentals driving the prices. One known and observable economics fundamental to consumer prices is the money supply. The nonstationarity in prices could also be caused by the nonstationarity of other unobserved economic fundamentals, rather than a rational bubble. Hence, the authors included two other time series in their tests, the monetary base and exchange rate in Argentina. Since both consumer prices and exchange rate are likely to be driven by common fundamentals, evidence of simultaneously change in these two series would suggest that the nonstationarity in prices is attributable to their market fundamentals. On the other hand, asynchronous changes across the two series may be explained by the presence of a rational bubble. For example, if both series switch simultaneously to the explosive regime, represented by  $s_t = 1$ , while the money process remains in the no-explosive regime ( $s_t = 0$ ), one can infer that the event is driven by some unobservable economic fundamental common to price and exchange rate, rather than by explosive rational bubbles. Conversely, when price switch to explosive regime whereas the two other series remains in the non-explosive regime, one can conclude there is a rational bubble in the price.

Again, the authors were able to identify rational bubbles presented in the consumer prices and exchange rates of Argentina.

### **III. Application of Switching ADF to Property Prices**

The property markets in many Asian countries boomed in the early 1990s, but busted following the South-East Asian financial crisis in late 1997. Markets reflecting this general trend are Hong Kong, Singapore, Malaysia, etc. An exception to this trend is Korea property market. The large up-swing in property prices during early 1990s in many of the Asian countries, and the recent rise in Korea property prices are generally taken as reflecting speculative bubbles in the popular press.

This paper intends to inquire into the possibility of existence of rational bubbles in the property markets of Hong Kong and Korea, using the switching ADF procedure.

#### 3.1 Data

A price and its associated rent series are selected for each market under consideration from CEIC database. In Hong Kong, these are the retail premise price and rent indices deflated by CPI. Each series make use of two data sets of different frequencies---the first set is quarterly data running from December 1980 to September 2000, the second monthly data stretching from January 1993 to January 2003. In order to combine them, we convert the first set into monthly data by cubic spline. Thus the first half of our data set, running from December 1980 to December 1992, consists of the splined output from the first data set, whereas the remaining half from the second data set. The raw data has 266 observations for both price and rent series. The series for Korea are CPI deflated

monthly housing price and housing rent indices between January 1986 and June 2003, with a total of 210 observations of raw data.

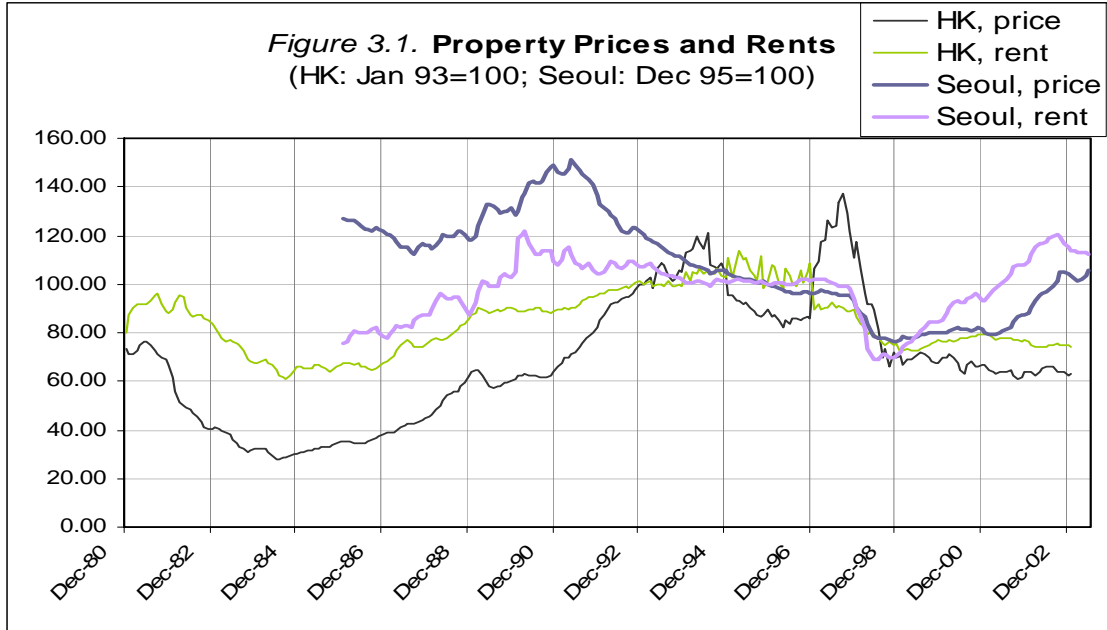

### 3.2 Estimation of the Switching ADF Regression Model<sup>3</sup>

A casual examination of figure one suggests that there might be three regimes governing the movement of each price series. In the first state, price is more or less stable or its movement is coupled by rent (e.g. Hong Kong after August 1998; Seoul between September 1987 and February 1990). We call such a state, preliminarily, one in which bubble is dormant. In the second state, price is rising sharply, with little or no corresponding movement in rent (e.g. Hong Kong between October 1993 and July 1994, and between December 1996 and September 1997; Seoul between February 1990 and May 1991). We call such a state one in which bubble is expanding. In the third state, price plunges, with little or no co-movement in rent (e.g. Hong Kong between July 1994 and June 1996, and between September 1997 and August 1998; Seoul between January 1986 and September 1987). We call such a state one in which the bubble is collapsing.

---

<sup>3</sup> For more details, please refer to James Hamilton (1994).

Source: CEIC database

Thus, the following ADF model is fitted to each of the four series

$$\Delta y_t = \mu^{st} + \phi^{st} y_{t-1} + \sum_{k=1}^K \psi_k^{st} \Delta y_{t-k} + \varepsilon_t \quad \varepsilon_t \text{ iid}, N(0, \sigma^2) \quad (3.2.1)$$

where  $s_t \in \{1, 2, 3\}$ , a state variable following the first order Markov Chain

$$\begin{aligned} & \Pr(s_{t+1} = j | s_t = i, s_{t-1} = i_1, \dots, \zeta_t) \\ &= \Pr(s_{t+1} = j | s_t = i) \\ &\equiv p_{ij} \end{aligned} \quad (3.2.2)$$

with  $\zeta_t = (y_t, y_{t-1}, \dots, y_1)$ , the information set available at time  $t$ , and  $p_{ij}$  the state transition probability. Equation (3.2.2) says that the probability distribution of  $s_{t+1}$  depends on past events only through the value of  $s_t$ .

The state variable  $s_t$  is not observed, but can be inferred using the discrete Kalman filter described by Hamilton (1994), and summarized below.

Rewrite equation (3.2.1) as

$$y_t = x_t' \beta_{st} + \varepsilon_t \quad \varepsilon_t \text{ iid}, N(0, \sigma^2) \quad (3.2.3)$$

Assume  $\mu^{st}, \phi^{st}, \psi_k^{st}, p_{ij}$  and  $\sigma$  are known with certainty. If the Markov chain is stationary and ergodic, the iteration to evaluate  $\Pr(s_t = i | \zeta_{t-1})$  ( $i=1,2,3$  and

$\sum_{i=1}^3 \Pr(s_t = i | \zeta_{t-1}) = 1$ ), can start at date  $t=1$  with the unconditional probabilities  $\boldsymbol{\pi}$ , where

$\boldsymbol{\pi}' = (\pi_1 \quad \pi_2 \quad \pi_3)$ , and  $\pi_i \equiv \Pr(s_t = i)$ .

We can evaluate  $\boldsymbol{\pi}$  by solving the system of two equations

$$\begin{aligned} \boldsymbol{\pi} &= F\boldsymbol{\pi} \\ \mathbf{1}'\boldsymbol{\pi} &= 1 \end{aligned} \quad (3.2.4)$$

where  $F$  is the matrix of state transition probabilities

$$F = \begin{pmatrix} p_{11} & p_{21} & p_{31} \\ p_{12} & p_{22} & p_{32} \\ p_{13} & p_{23} & p_{33} \end{pmatrix} \quad (3.2.5)$$

and

$$\mathbf{1}' = (1 \quad 1 \quad 1)$$

At step  $t$ , the inputs are  $\{\Pr(s_t = i|\zeta_{t-1})\}_{i=1}^3$  and the outputs are  $\{\Pr(s_{t+1} = j|\zeta_t)\}_{j=1}^3$ , with  $\Pr(s_1 = i|\zeta_0) = \pi_i$ . Given  $\Pr(s_t = i|\zeta_{t-1})$  and given the normality assumption, the conditional density function for  $y_t$  is

$$f(y_t | s_t = i, x_t, \zeta_{t-1}) = \frac{1}{\sqrt{2\pi\sigma^2}} \exp\left(-\frac{(y_t - x_t' \beta_i)^2}{2\sigma^2}\right) \quad (3.2.6)$$

Since  $x_t$  is predetermined

$$\Pr(s_t = i | x_t, \zeta_{t-1}) = \Pr(s_t = i | \zeta_{t-1})$$

Hence the joint density of  $y_t$  and  $s_t = i$ , given  $x_t$  and  $\zeta_{t-1}$

$$f(y_t, s_t = i | x_t, \zeta_{t-1}) = f(y_t | s_t = i, x_t, \zeta_{t-1}) \Pr(s_t = i | \zeta_{t-1}), \quad i = 1, 2, 3 \quad (3.2.7)$$

Thus the density of  $y_t$  conditional on  $x_t$  and  $\zeta_{t-1}$

$$f(y_t | x_t, \zeta_{t-1}) = \sum_{i=1}^3 f(y_t, s_t = i | x_t, \zeta_{t-1}) \quad (3.2.8)$$

By Bayse Rule, the optimal filter of  $s_t$  given  $\zeta_t$ , the information set available at time  $t$ , is

$$\Pr(s_t = i | \zeta_t) = \frac{f(y_t, s_t = i | x_t, \zeta_{t-1})}{f(y_t | x_t, \zeta_{t-1})} \quad (3.2.9)$$

and the prediction of  $s_{t+1}$

$$\Pr(s_{t+1} = j | \zeta_t) = \sum_{i=1}^3 p_{ij} \Pr(s_t = i | \zeta_t) \quad (3.2.10)$$

A more efficient inference about  $s_t$  can be obtained by using the entire set of information available to the researcher,  $\zeta_T$

$$\Pr(s_t = i | \zeta_T) = \sum_{i=1}^3 \Pr(s_t = i, s_{t+1} = j | \zeta_T) \quad (3.2.11)$$

where

$$\Pr(s_t = i, s_{t+1} = j | \zeta_T) = \Pr(s_{t+1} = j | \zeta_T) \frac{\Pr(s_t = i | \zeta_t) \Pr(s_{t+1} = j | s_t = i)}{\Pr(s_{t+1} = j | \zeta_t)} \quad (3.2.12)$$

$i, j = 1, 2, 3$

$\Pr(s_t = i | \zeta_T)$  is called the smoothed inference of the state variable. This smoothed probability sequence  $\{\Pr(s_t = i | \zeta_T)\}_{t=1}^T$  can be computed by backwards iteration. The iteration starts with  $\Pr(s_T = i | \zeta_T)$  obtained from the filtering process using equation (3.2.9).

So far we have assumed that  $\mu^{st}, \phi^{st}, \psi_k^{st}, p_{ij}$  and  $\sigma$  are known to us, where  $s_t = \{1, 2, 3\}$ .

But in fact these parameters need to be estimated. We can estimate them by maximizing the log likelihood function of the observed data using EM algorithm, since EM algorithm is an efficient approach (Hamilton, 1994). The log-likelihood function to be maximized is

$$LL = \sum_{t=1}^T \log f(y_t | x_t, \zeta_{t-1}), \text{ with } f(y_t | x_t, \zeta_{t-1}) \text{ given by (3.2.8), The steps of the estimation}$$

are given below.

*Step one:* make an arbitrary guess on  $\mu^{st}, \phi^{st}, \psi_k^{st}, p_{ij}$  and  $\sigma$ ;

*Step two:* calculate the smoothed probabilities of  $s_t$  using (3.2.3) to (3.2.12);

*Step three:* OLS regress  $y_t \sqrt{\Pr(s_t = i | \zeta_T)}$  on  $x_t \sqrt{\Pr(s_t = i | \zeta_T)}$ ,  $i = 1, 2, 3$ , which

gives ML estimates  $\tilde{\mu}^{st}, \tilde{\phi}^{st}, \tilde{\psi}_k^{st}$ , ( $k = 1, 2, \dots, K$ ).

*Step four:* update  $\sigma^2$  using the OLS residuals;

$$\tilde{\sigma}^2 = \frac{\sum_{st=1}^3 (y_t - x_t' \tilde{\beta}_{st})(y_t - x_t' \tilde{\beta}_{st})}{3 \times (T - N)} \quad (3.2.13)$$

where N: the number of parameters estimated.

*Step five:* update  $p_{ij}$

$$p_{ij} = \frac{\sum_{t=2}^T \Pr(s_t = j, s_{t-1} = i | \zeta_T)}{\sum_{t=2}^T \Pr(s_{t-1} = i | \zeta_T)} \quad (3.2.14)$$

*Step six:* update  $\pi$

$$\pi_i = \Pr(s_1 = i | \zeta_T) \quad (3.2.15)$$

*Step seven:* repeat step two to six until the parameters and the likelihood converge.

### 3.3. Asymptotic Properties of ML Estimators

Suppose  $\tilde{\theta}$  is the ML estimator of  $\theta$ , and  $\theta_0$  the true value of  $\theta$ , where

$\theta = \{ \mu^{st}, \phi^{st}, \psi_k^{st}, p_{ij}, \sigma \}$ . Subject to certain regularity conditions (Caines, 1988, Ch7),  $\tilde{\theta}$

is consistent and asymptotically normal, with limiting distribution

$$\sqrt{T} \varphi_{2D,T}^{\frac{1}{2}} (\tilde{\theta} - \theta_0) \xrightarrow{d} N(0, I) \quad (3.3.1)$$

i.e.

$$\tilde{\theta} \xrightarrow{d} N(\theta_0, T^{-1} \varphi_{2D,T}^{-1}) \quad (3.3.1')$$

where  $\varphi_{2D,T}$  is the information matrix from the sample of size T

$$\varphi_{2D,T} = -\frac{1}{T} E \left( \sum_{t=1}^T \frac{\partial^2 \text{Log} L_t}{\partial \theta \partial \theta'} \middle| \theta = \theta_0 \right) \quad (3.3.2)$$

$$\lim_{T \rightarrow \infty} \varphi_{2D,T} \xrightarrow{p} \hat{\varphi} = -\frac{1}{T} \left( \sum_{t=1}^T \frac{\partial^2 \text{Log} L_t}{\partial \theta \partial \theta'} \middle| \theta = \tilde{\theta} \right) \quad (3.3.3)$$

The reported standard errors for  $\tilde{\theta}$  are the square roots of the diagonal elements of

$$(T\hat{\varphi})^{-1} = - \left( \sum_{t=1}^T \frac{\partial^2 \text{Log} L_t}{\partial \theta \partial \theta'} \middle| \theta = \tilde{\theta} \right)^{-1}$$

### 3.4 Computing Hessian by Numerical Method (Wheatley, 2004)

In this experiment, we use the numerical approach to Hessian computation. Consider a continuous function  $f$ , and the value  $f(x + \Delta x)$ . By Taylor's expansion

$$f(x + \Delta x) \approx f(x) + f'(x)\Delta x + \frac{f''(x)}{2}(\Delta x)^2 \quad (3.4.1)$$

rearrange

$$f''(x) \approx \frac{f(x + \Delta x) - f(x) - f'(x)\Delta x}{(\Delta x)^2} \times 2 \quad (3.4.1')$$

Also consider the value  $f(x - \Delta x)$ . By Taylor's expansion

$$f(x - \Delta x) \approx f(x) - f'(x)\Delta x + \frac{f''(x)}{2}(\Delta x)^2 \quad (3.4.2)$$

which gives

$$f''(x) \approx \frac{f(x - \Delta x) - f(x) + f'(x)\Delta x}{(\Delta x)^2} \times 2 \quad (3.4.2')$$

Combining (3.4.1') and 3.4.2')

$$f''(x) \approx \frac{f(x - \Delta x) - 2f(x) + f(x + \Delta x)}{(\Delta x)^2} \quad (3.4.3)$$

Let  $f = LL$ , then

$$\frac{\partial^2 LL}{\partial \theta \partial \theta} \approx \frac{LL(\theta + \Delta) - 2 \times LL(\theta) + LL(\theta - \Delta)}{\Delta^2} \quad (3.4.4)$$

In our experiment, a range of values of  $\Delta$ , from  $10^{-1}$  to  $10^{-5}$ , are tried out to allow for variation in the values of log-likelihood function. The results are fairly stable under different choices of  $\Delta$ .

### 3.5 Lag Selection in ADF Regression

Consider

$$\Delta y_t = \alpha + \gamma y_{t-1} + \sum_{j=1}^p \delta_j \Delta y_{t-j} + \varepsilon_t$$

where  $p$  is to be determined.

Taking the general-to-specific procedure, we start by setting  $p = k$ , where  $k = k_{\max} \approx \sqrt{T}$ , and  $T$  is the size of the sample. Estimate the above equation by OLS, and test:

$$H_0: k = k_{\max} - 1$$

$$H_1: k = k_{\max}$$

if  $H_0$  is rejected, set  $k = k_{\max}$ . Otherwise, test:

$$H_0 : k = k_{\max} - 2$$

$$H_1 : k = k_{\max} - 1$$

...

Stop when  $H_0$  is rejected.

The test results are presented in the table below.

### 3.6 Smoothed State Probabilities

The smoothed probabilities computed using method described in section 3.2 suggests that only the first state is highly likely throughout the sample period for both price and rent series of Hong Kong and Seoul<sup>4</sup>. Refer to figure 3.2 through figure 3.5. This is consistent with the values of state transition probabilities, which show that there is a tendency for the DGPs to switch into the first state from other states, and that there is a lack of tendency to switch into other states from the first state. Refer to table 3.2.

However, the first state is not an absorbing state as the state probability is less than one (Hamilton, 1994). Given the large probability of the first state, we nevertheless investigate the possibility that the entire series is generated by parameters governing this state. We first obtain artificial data using those parameters. We then feed these artificial data to the same estimation procedure. But the results could not repeat what are shown in Figure 3.2 to 3.5.

---

<sup>4</sup> The estimation of a 2-state switching model also suggests only the first state is highly likely.

The maximum likelihood estimates of model parameters are listed in Table 3.3 to 3.6.

### 3.7 Unit Root Hypothesis Testing

The unit root test statistic is the t-ratio associated with  $\phi$ , under the null hypothesis of  $\phi = 0$ . The null distribution of this statistic is unknown but can be generated by bootstrapping. Since only the first state is likely for both Hong Kong and Seoul, we will bootstrap only the parameters associated with that state.

#### *3.7.1 The Theory and Practice of Bootstrap*<sup>5</sup>

The bootstrap is a method for estimating the distribution of an estimator or test statistic by re-sampling one's data. It amounts to treating the data as if they were the population for the purpose of evaluating the distribution of interest. Under mild regularity conditions, the bootstrap yields an approximation to the distribution of an estimator or test statistic that is at least as accurate as the approximation obtained from first-order asymptotic theory. Thus, the bootstrap provides a way to substitute computation for mathematical analysis if calculating the asymptotic distribution of an estimator or statistic is difficult.

In fact, the bootstrap is more accurate in finite samples than first-order asymptotic approximations and does not entail the algebraic complexity of higher-order expansions.

---

<sup>5</sup> Please refer to *Handbook of Econometrics*, vol. 5, Ch. 52.

The bootstrap is important in hypothesis testing. First-order asymptotic theory often gives poor approximations to the distributions of test statistics with the sample sizes available in applications. As a result, the nominal probability that a test based on an asymptotic critical value rejects a true null hypothesis can be very different from the true rejection probability (RP). The bootstrap often provides a tractable way to reduce or eliminate finite-sample errors in the RP's of statistical tests.

The method nevertheless has its own limitations<sup>6</sup> and should not be used blindly, but it works well in general. The readers are referred to Handbook of Econometrics, Volume 5 for details on the sampling procedure and the consistency of the bootstrap.

### 3.8.4 Our application

The steps of bootstrapping in our particular case are described below.

*Step one:* save the ML parameter estimates  $\tilde{\theta}$  and residuals  $\{\tilde{\varepsilon}_t\}_{t=1}^T$ ;

*Step two:* construct an artificial random variable  $u \text{ X.i.i.d. } N(0, \tilde{\sigma}^2)$ , where  $\tilde{\sigma}^2$  the ML estimates of  $\sigma^2$

*Step three:* take a random draw from  $u$ , denote as  $u_1^{(1)}$ , and set

$$\Delta y_1^{(1)} = \tilde{\mu} + \sum_{k=1}^K \tilde{\psi}_k \Delta y_{-k} + u_1^{(1)}$$

$$\Delta y_2^{(1)} = \tilde{\mu} + \tilde{\psi}_1 \Delta y_1^{(1)} + \sum_{k=2}^K \tilde{\psi}_k \Delta y_{-k} + u_1^{(1)}$$

---

<sup>6</sup> Handbook of Econometrics, vol. 5, Ch 52.

...

$$\Delta y_T^{(1)} = \tilde{\mu} + \sum_{k=1}^K \tilde{\psi}_k \Delta y_{T-k}^{(1)} + u_1^{(1)}$$

where:  $\Delta y_t^{(1)}$  : simulated values of  $\Delta y_t$ ;

$\Delta y_{-k}$  : actual observed values of  $\Delta y_t$ ;

$\tilde{\mu}, \tilde{\psi}_k$  : ML estimates.

This gives a full sample  $\{y_t^{(1)}\}_{t=1}^T$ .<sup>7</sup>

*Step four:* fit the artificial sample to equation (3.2.1), producing estimates of model parameters,  $\tilde{\theta}^{(1)}$ , and their associated t-ratios.

*Step five:* repeat step three and four 520 times, gives  $\{\tilde{\theta}^{(i)}\}_{i=1}^{520}$  and their associated t-ratios. The 95% confidence interval for ML estimates  $\tilde{\theta}$  and its t-ratio constructed under the null hypothesis include 95% of the values of  $\tilde{\theta}^{(i)}$  and their associated t-ratios respectively.

#### 4. Adjustment for Non-spherical Disturbances

In (3.2.1), it is assumed that  $\varepsilon_t$  has a spherical distribution, whereas in fact the ML residuals displays ARCH pattern. Refer to figure 4.1 and 4.2.

Notice, by assuming normality, the ML estimator is also the OLS estimator, which is consistent in the presence of non-spherical disturbances but inefficient, and hypothesis

---

<sup>7</sup> T=206 for Seoul and 255 for Hong Kong.

testing based on standard covariance matrix will not be appropriate. To be specific, consider

$$y = X\beta + \varepsilon$$

where

$$E[\varepsilon] = 0$$

$$E[\varepsilon\varepsilon'] = \sigma^2\Omega$$

and  $\Omega$  is a positive definite matrix.

In large sample, if  $p \lim \frac{X'X}{T}$  and  $p \lim \frac{X'\Omega X}{T}$  (T is the size of sample) are finite positive definite matrices, OLS estimator is consistent. However, the asymptotic covariance matrix is not  $\sigma^2(X'X)^{-1}$ . In general, if the regressors are sufficiently well behaved and off-diagonal terms in  $\Omega$  diminish sufficiently rapidly, the asymptotic covariance matrix of OLS estimator is given by

$$Asy.Var(\beta) = \frac{\sigma^2}{T} \left( p \lim \frac{X'X}{T} \right)^{-1} \left( p \lim \frac{X'\Omega X}{T} \right) \left( p \lim \frac{X'X}{T} \right)^{-1} \quad \text{Equation 1}$$

Thus inferences based on  $\sigma^2(X'X)^{-1}$  will be misleading and the familiar inferences procedures based on F- and t- distributions will no longer be appropriate.

#### 4.1 Robust Estimation of Asymptotic Covariance Matrices

The estimator of the asymptotic covariance matrix is

$$V_{OLS} = \frac{1}{T} \left( \frac{X'X}{T} \right)^{-1} \left( \frac{X'(\sigma^2\Omega)X}{T} \right) \left( \frac{X'X}{T} \right)^{-1}$$

However  $\sigma^2\Omega$  is unknown. Denote

$$\Sigma = \sigma^2\Omega$$

$\Sigma$  has  $K(K+1)/2$  ( $K$  is the number of parameters in  $\beta$ ) unknown elements in the matrix

$$p \lim Q_* = p \lim \frac{1}{T} \sum_{i=1}^T \sum_{j=1}^T \sigma_{ij} x_i x_j'$$

Since OLS estimator  $\tilde{\beta}$  is a consistent estimator of  $\beta$ , the OLS residuals  $e_t$  are point-wise consistent estimators of their population counterparts  $\varepsilon_t$ . The general approach, then, will be to use  $X$  and  $e$  to devise an estimator of  $Q_*$ .

Consider the heteroscedasticity case first. We seek an estimator of

$$Q_* = \frac{1}{T} \sum_{i=1}^T \sigma_i^2 x_i x_i'$$

White (1980) has shown that under very general conditions the estimator

$$S_0 = \frac{1}{T} \sum_{i=1}^T e_i^2 x_i x_i' \tag{Equation 2}$$

has

$$p \lim S_0 = p \lim Q_*$$

Hence the White heteroscedasticity consistent estimator

$$Est.Asy.Var(\beta) = T(X'X)^{-1} \left( \frac{1}{T} \sum_{i=1}^T e_i^2 x_i x_i' \right) (X'X)^{-1} \tag{Equation 3}$$

can be used to estimate the asymptotic covariance matrix of  $\tilde{\beta}$ .

This result implies that without actually specifying the type of heteroscedasticity we can still make appropriate inferences based on the results of least squares. This is especially useful if we are unsure of the precise nature of the heteroscedasticity, which is probably case most of the time.

The extension of White's result to the more general case of autocorrelation is much more difficult. Newey and West (1987) have devised an estimator of the form

$$\hat{Q}_* = S_0 + \frac{1}{T} \sum_{l=1}^L \sum_{t=l+1}^T w_l e_t e_{t-l} (x_t x_{t-l}' + x_{t-l} x_t')$$

where

$$w_l = \frac{1}{(L+1)}$$

The Newey-West autocorrelation consistent covariance estimator is simple and relatively easy to implement. However, in general, there is little theoretical guidance as to the choice of  $L$ .

#### 4.2 Test and Model the ARCH Effect

To examine the ARCH effect in the ML residuals of our model, we conduct the following test: H0: ARCH(q) versus H1: ARCH(0). The LM test statistics is  $TR^2$  which has a  $\chi^2$  distribution with degree of freedom equals to q.  $R^2$  is the goodness of fit measure of the regression

$$e_t^2 = \left[ \alpha_0 + \sum_{i=1}^q \alpha_i e_{t-i}^2 \right]$$

where  $e_t$  is the ML residual. The test statistics for ARCH(4)<sup>8</sup> are given Table 4.1, which are highly significant in all cases.

Since the ML residuals display ARCH(4) patterns, we estimated the following model

$$\varepsilon_t = u_t \left[ \alpha_0 + \alpha_1 \varepsilon_{t-1}^2 + \alpha_2 \varepsilon_{t-2}^2 + \alpha_3 \varepsilon_{t-3}^2 + \alpha_4 \varepsilon_{t-4}^2 \right]^{\frac{1}{2}}$$

where

$$u_t \xrightarrow{d} iid(0,1)$$

and

$$\begin{aligned} E[\varepsilon_t | \varepsilon_{t-1}] &= 0 \\ \text{Var}[\varepsilon_t | \varepsilon_{t-1}] &= \alpha_0 + \alpha_1 \varepsilon_{t-1}^2 + \alpha_2 \varepsilon_{t-2}^2 + \alpha_3 \varepsilon_{t-3}^2 + \alpha_4 \varepsilon_{t-4}^2 \\ \text{Cov}[\varepsilon_t, \varepsilon_{t-i}] &= 0, \quad \text{for } i > 1 \end{aligned} \quad \text{Equation 4}$$

The following estimation procedures are used (refer to Greene Ch12.)

1. Regress the squared ML residuals on its four lagged values to give the first estimates of  $\alpha_i$ , denoted by  $a_i$ ,  $i = 0, 1, \dots, 4$ .
2. Compute the conditional variances using  $\hat{\sigma}_t^2 = a_0 + a_1 \varepsilon_{t-1}^2 + a_2 \varepsilon_{t-2}^2 + a_3 \varepsilon_{t-3}^2 + a_4 \varepsilon_{t-4}^2$ .

$$\text{Run the regression } \left( \frac{e_t^2}{\hat{\sigma}_t^2} - 1 \right) = d_0 \frac{1}{\hat{\sigma}_t^2} + d_1 \frac{e_{t-1}^2}{\hat{\sigma}_t^2} + d_2 \frac{e_{t-1}^2}{\hat{\sigma}_t^2} + d_3 \frac{e_{t-1}^2}{\hat{\sigma}_t^2} + d_4 \frac{e_{t-1}^2}{\hat{\sigma}_t^2};$$

---

<sup>8</sup> The choice of ARCH(4) is based on observations of plots of ARCH of different lags, not based on formal tests, hence is a bit arbitrary and can be strengthened by imposing more formal tests. However, the main implications of the ARCH pattern on unit root tests should not be affected by incorporating longer lags.

3. The asymptotically efficient estimator of  $\alpha$  is given by  $\hat{\alpha} = a + d$ , where  $\hat{\alpha}, a, d$  are all  $5 \times 1$  vectors. and the  $Asy.Var(\alpha) = 2(Z'Z)^{-1}$ , where  $Z : T \times 5$  and  $z_t = [1 \quad e_{t-1}^2 \quad e_{t-2}^2 \quad e_{t-3}^2 \quad e_{t-4}^2]$ .

The estimation results for the four time series are summarized in Table 4.2 to 4.5, which show that all the ARCH parameters are highly significant. The squared ML residuals and their predicted values using the estimates of ARCH(4) model are plotted in Figure 4.3 to 4.6. These plots demonstrate that the estimated models capture the patterns of the ML residuals.

#### 4.3 Calculate the Standard Errors for Model Parameters

The previous section shows that [Equation 2](#) is a reasonable description of the processes of the ML residuals. Since the covariance is zero between  $\varepsilon_t$  and  $\varepsilon_{t-i}$  for all  $i \geq 1$  in this model, the ML exhibit heteroscedasticity but not autocorrelations. Hence we may use the White heteroscedasticity consistent estimator for the asymptotic variance of model parameters

$$Est.Asy.Var(\beta) = T(X'X)^{-1} \left( \frac{1}{T} \sum_{t=1}^T e_t^2 x_t x_t' \right) (X'X)^{-1}$$

Tables 4.6 to 4.9 display the standard errors for model parameters in each state and their associated t-ratios, using White's estimator.

#### 4.4 Bootstrapping

In this section, we incorporate ARCH(4) pattern of the ML residuals into our bootstrapping procedure in generating the distribution of parameters and their associated t-ratios. 10,000 replications are used for each series. Only states one is considered as the probability of state one dominates throughout the sample period for each series.

To examine the robustness of the bootstrapping exercise, we display table 4.10 to 4.17 the distribution of parameters and their associated t-ratios not only for  $\phi$ , the parameter of interest in terms of unit root testing, but also for all the other parameters. These tables show that, in general, the distributions of parameters are not strictly symmetric, but the skewness is not severe except for the constant term. The t-test shows that the null hypothesis of  $\beta = 0$  can be rejected for all parameter estimates at 99% level. Given these results, we can confidently say that the null hypothesis of unit root is rejected at 99% significance level in favor of stationarity.

### **5. Conclusions**

In this paper, we have applied the unit root test to examine the question whether or not the prices of interests contain speculative bubbles. This is done by comparing the properties of a price series with that of its associated rent series. Theoretically speaking, if price exhibit explosive behavior whereas rent does not, then one may infer that the price contains speculative bubbles. If both price and rent exhibit explosive behavior at the same time, then, the explosiveness in price is driven by fundamentals rather than

speculative bubbles. Since such tests are typically weak in power when there are structural breaks in the time series, we incorporate Markov-switching process to capture the possibility of structural change.

Our estimation show that, all the four series considered are dominated by one state, that is, there is little evidence of regime switch in the structures of the data generating processes. As the ML residuals exhibit heteroscedasticity, we incorporate the non-spherical disturbances in our bootstrapping which is used to generate critical values for our test statistics. The critical values used for tests are generated with 10,000 replications. The evidences of tests show no sign of speculative bubble in any of the two price series.
